## **Conclusions**

1. Non-dipper circadian blood pressure profile is significantly frequent in patients with essential hypertension, while dipper circadian blood pressure profile is prevalent in normotensive individuals.
2. Different from the normotensive individuals, in patients with essential hypertension was established significantly higher levels of erythrocyte aggregability, platelet aggregative and adhesive activity, fibrinogen concentration, hematocrit level and plasma viscosity, which indicates on the high possibility of thrombogenesis.
3. Besides microcirculatory level, in patients with essential hypertension were appeared disturbances on the macrocirculatory – conduit artery – level; namely, mean value of endothelium-dependent vasodilatation was significantly correlated with the state of endothelial function.
4. There was established significantly high negative correlation between haemorheological parameters on the one hand and endothelium-dependent and endothelium-independent vasoconstriction on the other hand.
5. There was established, that in patients with essential hypertension dipper circadian blood pressure profile is replaced by non-dipper circadian profile, which in comparison with dippers has more sharply expressed haemorheological disorders and endothelial dysfunction.
6. Because of the deep haemorheological disturbances and endothelial dysfunction, patients with non-dipper essential hypertension have to be considered as the high risk group for development of vascular complications while critical hours period of night and morning.
7. It was established, that duration of arterial hypertension does not correlate with the stage of endothelial dysfunction. At the same time, there were appeared correlations between duration and stage of arterial hypertension and dysfunction of vascular musculature.
8. Via studying an action of the duration and stage of arterial hypertension on haemorheological indices we established, that patients with 2<sup>nd</sup> stage of essential hypertension and duration more than 7 years have significantly higher platelet and erythrocyte aggregative activity, fibrinogen concentration and plasma viscosity level.
9. In our study there was not appeared difference in the endothelial dysfunction's degree according to the duration and stage of essential hypertension. Therefore, muscular dysfunction was more clearly appeared in hypertensive patients with 2<sup>nd</sup> stage and duration more than 7 years.

10. Our study confirmed that non-dipper patients compared with dippers have higher stage of arterial hypertension and longer duration of it. In this group of patients absolute level of vasodilatatory response on reactive hyperemia test was 3-folds lower than it was in dipper hypertensive patients. Consequently, reactive hyperemia mediated vasodilatation have to be considered as an assessment stress-test of vascular reactivity in the contingent of this group.
